## Abstract

In this work we consider two types of events, determined by decreases in  $D_{st}$  below a threshold value or increases in the  $\rho_{eq}$  above a threshold value on 1-hour and 1-day time scales using the ? dataset. From the  $D_{st}$  events, we find that there is no statistically significant relationship between either solar wind or geomagnetic activity under conditions of strong geomagnetic activity when hourly or daily averages of  $\rho_{eq}$  are considered. Although very large geomagnetic storms have been observed to correspond to large increases in the plasma trough mass density, in general  $\rho_{eq}$  following the onset of a geomagnetic storm does not depend on the storm intensity or the solar wind parameters  $B_z$  and  $P_{dyn}$ . From the  $\rho_{eq}$  events, we find a weak dependence on  $B_z$  after the onset of an event, with higher average  $B_z$  six hours after the event onset corresponding to larger  $\rho_{eq}$  events.

---

## 1 Introduction

The plasma trough is a transition region between the higher density and lower temperature plasmasphere and the lower density and higher energy magnetosphere [Mayr and Volland, 1968]. Inside of the plasmopause, the density is primarily due to ionospheric photoionization; outside of the plasmopause, the density has contributions from the co-rotating plasmasphere and Earthward convecting magnetosphere plasmas.

The dependence of the plasmopause location on geomagnetic activity was observed as early as ?. There are well-validated models of the plasmopause boundary, as a function of  $L$ ,  $MLT$ , and geomagnetic activity (Lemaire [1998], Moldwin et al. [2002], O'Brien and Moldwin [2003]). Models also exist for the plasmasphere density (Gallagher et al. [1988]; Lemaire [1998]).

The dependence of the plasma trough density on geomagnetic and solar wind conditions has not been extensively studied until the past decade (Takahashi et al. [2006]; Takahashi et al. [2010]; ?). Earlier works that considered profiles of electron number density found a significant dependence on the plasmasphere

boundary on geomagnetic activity (?; ?), but there the relationship between geomagnetic activity and density in the plasma trough was not explicitly considered.

Takahashi et al. [2006] estimated magnetospheric mass density using measurements from the CRRES satellite during a 73-day period in 1991 (observations were made when CRRES was in an elliptical, near equatorial orbit and primarily in the plasma trough region). They found that the average ion mass,  $M = \rho/n_e$ , had some correlation with geomagnetic activity, with more negative hourly  $D_{st}$  values corresponding to higher  $M$  and 1.5- and 3-day averages of  $K_p$  corresponding to higher  $M$  (3-hour averages of  $K_p$  had little visual correlation with  $M$ ). The mass density estimates were obtained from CRRES observations in the MLT range of 12:00 and 18:00 with most observations having  $L$  between 5 and 7  $R_E$ .

Denton et al. [2006] found a weak relationship between  $D_{st}$  and  $K_p$  and the field line distribution of  $\rho$  using observations of the first three toroidal Alfvén harmonic frequencies for  $L$  in the range of 6-8  $R_E$ . A more pronounced peak in the distribution along a field line near the equator was found for lower  $D_{st}$  and larger  $K_p$ . The equatorial value of  $\rho$  appeared identical for the bins of  $D_{st}$  (-142 to -31 nT and -31 to 37 nT) and  $K_p$  (1.5 to 3.4 and 3.4 to 5.9)

considered .

Takahashi et al. [2010] developed a mass density dataset using measurements from the Space Environment Monitor instruments on the Geostationary Operational Environmental Satellites (GOES) satellites from 1980 through 1992, with most measurements in the range of  $L = 6.8 \pm 0.2 R_E$ . The mass density  $\rho$  was estimated using the the Alfvén wave velocity relationship,  $V_A = B/\sqrt{\mu_0 \rho}$  a magnetic field model, and a numerical solution to a wave equation with an ionospheric boundary and the assumption of a zero resistance ionosphere. The equatorial mass density,  $\rho_{eq}$ , was derived from the estimated mass density using a power law dependence on the geocentric distance to the field line of the observation,  $R$ ,  $\rho = \rho_{eq} L / (R/R_E)$ . They found a high correlation ( $\sim 0.93$ ) between 27-day averages of F10.7 and 27-day medians of  $\rho_{eq}$ .

Takahashi et al. [2010] noted that downward spikes in the  $D_{st}$  index coincided with significant changes in  $\rho_{eq}$  for  $L$  near  $6.8 R_E$ . For five storms, two had  $\rho_{eq}$  spikes after the  $D_{st}$  drop, two had  $\rho_{eq}$  spikes before the drop, and one showed little change in  $\rho_{eq}$ . A key result was that when daily-averaged measurements were considered, an enhancement in  $\rho_{eq}$  appeared on the same day as minimum  $D_{st}$ .

Yao et al. [2008] studied the relationship between  $D_{st}$  and the number density of low-energy  $O^+$  in different regions (ring current and plasma sheet) using the TEAMS and ESA instruments on the low-altitude and high-inclination orbiting FAST satellite and found that the average  $N_{O^+}$  across the sampled L-shells (2-14) had a strong correlation (0.88) with the minimum  $D_{st}$  of the storm. Although the correlation in the plasma trough was not calculated, the data presented for four events show that the variations in  $N_{O^+}$  tended to appear near  $D_{st}$  minimum ( $\pm 2$  hours).

? ...

The results in the papers discussed indicate that (1) the mass density in the plasma trough region is best correlated with F10.7 and (2) there exists a much weaker relationship between mass density and the geomagnetic activity indices  $K_p$  and  $D_{st}$ . In this work we consider the dependence of mass density estimates in the Takahashi et al. [2010] and attempt to identify and statistically characterize the relationship between geomagnetic activity with mass density in

the plasma trough region. In addition, we attempt to identify solar wind processes that may drive changes in mass density.

There are several issues that are addressed in detail: (1) the plasma density measurements are sparse, (2) The plasma trough density has a high correlation with F10.7, and geomagnetic and solar wind parameters also correlate with F10.7, (3) the dependence of mass density on the north/south component of the solar wind magnetic field is expected to be nonlinear. For northward IMF, corresponding to low solar wind driving of the magnetosphere, the plasmasphere can expand past geosynchronous orbit where trough estimates of mass density are made resulting in an increase in observed density that are not due to solar wind driving; for southward IMF, events studies have shown an increase in mass density associated with strong southward IMF and enhanced magnetospheric activity (Takahashi et al. [2010]; Yao et al. [2008]).

Issue (1) is addressed by considering in detail the number of observations that are used in epoch averages around the time of two types of events, decreases in  $D_{st}$  below a threshold, and increases in  $\rho_{eq}$  above a threshold. Issue (2) is addressed using various methods to remove or isolate the F10.7 dependence. Issue (3) is addressed by considering epochs and linear correlations independent of the direction of the IMF along with separation of the epoch averages based on the northward and southward IMF.

In addition, we consider the influence of time averaging by comparing results using daily means and medians and hourly means and medians of solar wind and magnetospheric parameters.

## 2 Data Preparation and Overview

The parameters  $\rho_{eq}$  and  $F_{10.7}$  used in this work are from the dataset of Denton [2007], which was used in Takahashi et al. [2010]; data are available from 1980 through 1991 from GOES 2,3,5, 6 and 7. All other parameters used are from Kondrashov et al. [2014] from 1972 through 2013, which are on a 1-hour time grid.  $\rho_{eq}$  is the inferred equatorial mass density based on the 3rd harmonic toroidal frequency of magnetic field measurements as described in Takahashi et al. [2010]. The smallest cadence for  $\rho_{eq}$  values is 10 minutes. To compute an hourly median over the same interval for which the solar wind parameters were averaged, the median of all  $\rho_{eq}$  values in a given hour window was used. Fill (NaN) values were used for

hours in which no measurements were available. In cases where  $\rho_{eq}$  was available from multiple GOES satellites at the same time, the value from GOES 6 was selected. In the dataset, measurements from GOES 6 had the longest time span of coverage. An overview of the data used is shown in Figure 1.

In this work, events are defined to occur when  $D_{st}$  or  $\rho_{eq}$  crosses a threshold value, as indicated by horizontal dashed lines in their respective panels of Figure 1.

Figure 2 shows the long-term trends of  $\log(\rho_{eq})$  from GOES 6 and  $F_{10.7}$  computed using the median values in 27-day non-overlapping windows. A scatter plot of these two lines is shown in the lower panel of Figure 2. The linear correlation for GOES 6 using all measurements is found to be 0.94, which is the same value documented by Takahashi et al. [2010] who used measurements from all satellites in the time interval of 1980 through 1991 using the constraint  $0600 \leq MLT \leq 1200$ ,  $K_{p3d} \geq 1.0$  and  $D_{st} \geq -50$  nT. Our 27-day correlations for GOES 2, 5, and 7 are 0.81, 0.78, and 0.87, and the time range of coverage of measurements from these satellites are 1980-01-01/1983-05-16, 1983-01-01/1987-02-28, and 1983-05-27/1991-08-29 respectively.

### 3 Epoch Average Results

Two types of events are considered. The first is a drop in the  $D_{st}$  index **Cite Kyoto** below the threshold of -50 nT. These types of events are considered in order to determine if there is a well-defined  $\rho_{eq}$  dependence on geomagnetic activity/storms as indicated by  $D_{st}$  index. It is expected that the plasmasphere will exhibit two responses near these threshold crossings. First is the movement of the plasmasphere earthward (Lemaire [1998]) and the second is a possible change in density due to magnetospheric processes.

The second type of event is an increase in  $\rho_{eq}$  above a threshold of 20 amu/cm<sup>3</sup>. It is expected that these increases will typically occur after period of quiet geomagnetic activity. In this case, the plasmopause boundary may move outward past geosynchronous orbit and the increase will be due to measurements being made inside the plasmopause. A second possible reason for the increase could be due to magnetospheric processes.

#### 3.1 $D_{st}$ Events

Our first analysis uses data only from the time interval 1989-1991, which corresponds with the interval

used in the analysis in Takahashi et al. [2010]. In this interval, there were 329  $D_{st}$  events and 70  $\rho_{eq}$  events. For both types of events, the hour of the threshold crossing defines the zero epoch time, and for each event, 4 · 24 hours were considered before each event and 8 · 24 hours after each event. To compute the epoch averages on a daily time scale, the median value of all available measurements for all events centered on a window of  $\pm 12$  hours of the epoch zero hour was computed, and these averaging windows were shifted in increments of 24 hours. Similar results are obtained if we first reduce each event time series to have a 1-day cadence by computing medians in 1-day bins and then compute the medians across events. Error bars for each parameter are the standard deviation of the values used in computing the median divided by the square root of the number of values used.

The stack plot in the upper panel of Figure 3 shows the epoch averages for these events. The minimum  $D_{st}$  median is -48 nT. Consistent with Takahashi et al. [2010],  $D_{st}$  events correspond to elevated  $\rho_{eq}$ , although the magnitude of increase observed here is 1.5 amu/cm<sup>3</sup> (from 18 to 19.5 amu/cm<sup>3</sup>) instead of the increase of  $\sim 10$  amu/cm<sup>3</sup> found in Figure 11 of Takahashi et al. [2010]. The vertical green bars in the  $\rho_{eq}$  plot show the number of  $\rho_{eq}$  values that were used to compute the medians and error bars. For the non- $\rho_{eq}$  medians, the number of measurements used in computing the medians is typically equal to the number of events, which is much larger than the number of  $\rho_{eq}$  values as we used all available measurements instead of restricting to only values where a non-fill  $\rho_{eq}$  value existed.

In the lower panel of Figure 3 it is shown that the trends seen in the analysis of 1989-1991 also hold for the entire span of measurements from GOES 6, which spans 1983-1991 - a small elevation on the day of the event relative to the day before and day after, with median averages after the day of the event being slightly lower than that before.

To determine if the magnitude of the density medians on a given day were statistically different than another day, we used a two-population t-test. For the interval of 1989-1991, corresponding to the top panel of 3, the null hypothesis that any of the medians from days -1, 0, and 1 are different from each other is rejected with a maximum p value of. The results are shown in Table ??.

These tests indicate that there is not a statistically significant change in medians of  $\rho_{eq}$  on the day before

and day after a threshold crossing in  $D_{st}$ .

Days p -1 and 0 -1 and 1 0 and 1

Caption: Results of test on different between means of  $\rho_{eq}$  shown in the top panel of ?? on days near or on the day of a  $D_{st}$  event. A difference in the means can be rejected with a probability of false rejection of  $p$ .

Days p -1 and 0 -1 and 1 0 and 1

Caption: Results of test on different between means of  $\rho_{eq}$  shown in the bottom panel of ?? on days near or on the day of a  $D_{st}$  event.

Because the dynamics of the magnetosphere take place on a time scale of less than one day, we have also considered hourly averages as shown in the top panel of Fig. 4. A total of 668 events were found in the interval of May 1983 through August 1991 with an average duration of 9 hours and a median duration of 3 hours. The error bars were computed in the same way as Fig. 3. In this plot, the overall trend is similar to that found in the bottom panel of Fig. 4 -  $\rho_{eq}$  is slightly elevated at the time of the threshold crossing of  $D_{st}$  with respect to the values one day before and after, but the elevation is small and in general not statistically significant. At this timescale no obvious change in mass density at hourly timescale is visible. This points to an issue with only looking at long-timescale trends between density and  $D_{st}$ , and allows for the possibility that other factors are influencing the long term correlation because there is no obvious connection on a short timescale. One possibility is that, as suggested in Takahashi et al. [2010],  $F_{10.7}$  plays a significant role in driving long term density values which biases the long-term correlation of density and  $D_{st}$ .

The bottom panel of Fig. 4 contains the events shown in the top panel under the constraint that  $D_{st}$  remained below -50 nT for at least twelve hours after the event onset time. In the time period of elevated mass density within 12 hours of the start of the event, there were an average of X samples per hourly interval. This result is consistent with previous observations of large mass density spikes in the plasma trough region during large geomagnetic storms (Yao et al. [2008]; Takahashi et al. [2010] and the observation that solar wind parameters have very little correlation independent of  $F_{10.7}$  (?). To determine of this relationship can be observed in the events of the top

panel of Fig. 4, we sorted the events by the average  $D_{st}$  values in the time interval of 0-12 hours, split the events in two and recomputed the epoch averages of  $\rho_{eq}$ . The result is that there is no statistically significant difference in the mass density epoch averages for large versus small storms. This indicates that to confirm the  $\rho_{eq}$  dependence on large geomagnetic storms would require a dataset with a much larger number of strong geomagnetic storms.

### 3.2 $\rho_{eq}$ Events

An alternative type of event can be defined that corresponds to large increases in  $\rho$ . Figure 5 shows the epoch time series for events in which an increase of  $\rho_{eq}$  above 20 amu/cm<sup>2</sup> defines the start of the event. In finding  $\rho_{eq}$  events, all fill values were replaced with linearly interpolated values. **Not including  $\rho_{eq}$  events?**

Here we see that such events tend to be associated with positive  $B_z^{IMF}$  and low geomagnetic activity (?).

To determine if the sign of  $B_z^{IMF}$  influences the  $\rho$  epoch time series, we separated the events by the average of  $B_z^{IMF}$  in a time window of 4 hours.

Figure (a) shows the epoch curves for  $B_z^{IMF} \geq 0$  (257) events and  $B_z^{IMF} \leq 0$  (139) have no statistically significant difference.

#### 4 Figures

Figure 1: Overview of data used in this article. The top four panels show parameters from [Kondrashov et al. \[2014\]](#) and the bottom panel contains  $\rho_{eq}$  based on GOES 6 measurements from [Denton \[2007\]](#) after interpolation and averaging described in the text. Dashed horizontal lines in the  $D_{st}$  and  $\rho_{eq}$  panels indicate sample event cutoff thresholds of  $D_{st} = -50$  nT and  $\rho_{eq} = 20$  amu/cm<sup>3</sup> considered in Section 3.

Figure 2: Top: 27-day non-overlapping medians of  $F_{10.7}$  and  $\log(\rho_{eq})$  from GOES 6. Bottom: Correlation between  $\log(\rho_{eq})$  and  $F_{10.7}$  using medians in non-overlapping hour, day, and 27-day windows.

Figure 3:  $D_{st}$  events from GOES 6 using daily medians. Top: Events in the interval 1989-1991; compare to Takahashi et al. [2010] Fig. 11. Bottom: Events in the interval 1983-1991.

Figure 4:  $D_{st}$  events from GOES 6 using hourly medians. Top: Events in the interval 1983-1991; compare to bottom panel Fig. 3. Bottom: Same as Top except for constraint that  $D_{st}$  stayed below  $-50$  nT for at least 12 hours after crossing below  $-50$  nT.

Figure 5:  $\rho_{eq} > 20$  amu/cm<sup>3</sup> events from GOES 6 using hourly medians. As described in the text, there is no statistically significant dependence of the  $\rho_{eq}$  plot on  $B_z$  in the time interval of  $\pm 2$  hours around the event.

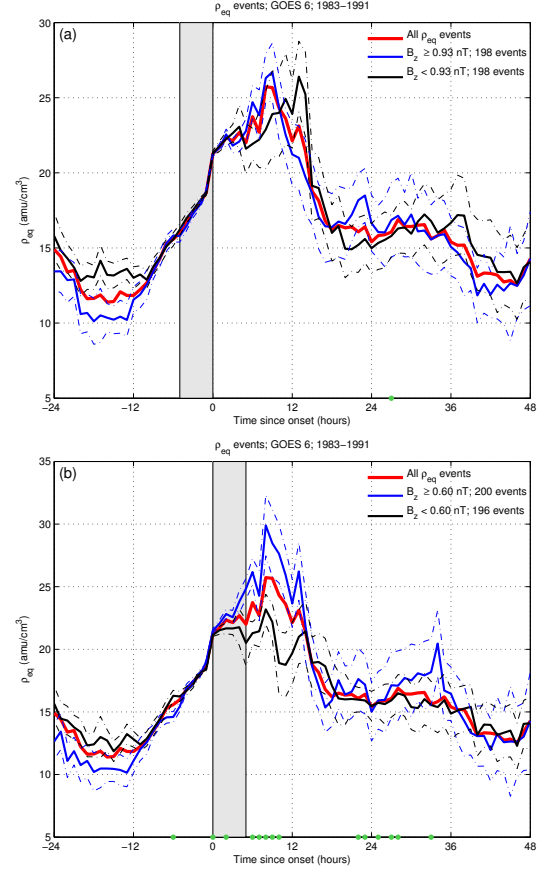

Figure 6: Binning  $\rho_{eq}$  events by  $B_z$  value (a) at onset and four hours before, and (b) at onset and four hours after.
